Distilling Sparse Linear Algebra

ALEKSEY TYURIN, Saint Petersburg State University, Russia

1 INTRODUCTION

Linear algebra is a great instrument for solving a wide variety of problems utilizing matrices and vectors for data representation and analysis with the help of highly optimized routines. But in reality matrices in many applications are often sparse, incurring both computational and storage inefficiencies, requiring an unnecessarily large storage, occupied by zero elements, and a large number of operations on zeroes, where the result is obviously known beforehand. The traditional approach to address these inefficiencies is to compress the matrix and store only the non-zero elements, and then operate only on the non-zero values. It makes the techniques of matrix compressed representation and sparse linear algebra to be the effective way of tackling problems in areas including but not limited to graph analysis [13], computational biology [18] and machine learning [14].

GraphBLAS [3] standard defines sparse linear algebra building blocks useful to express algorithms for already mentioned areas in a uniform way in terms of sparse matrix and vector operations over some semiring. These include matrix/vector multiplication, element-wise operations (e-wise for short), kronecker product, masking, i.e. taking a subset of elements that satisfies the mask or its complement, and are sufficient to express a lot of algorithms, e.g. *PageRank*, *Breadth-First-Search*, *Sparse Deep Neural Network* [6].

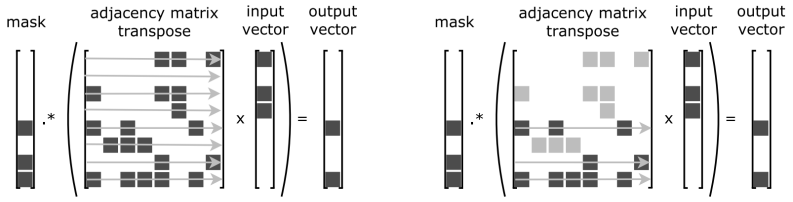
However sparse computations appear to have a low arithmetic-to-memory operations intensity, meaning that the main bottleneck of sparse-algorithms is the sparse representation itself that induces pointer-chasing. Thus, a number of optimizations have been identified [24], whose aim is to reduce the intensity of memory accesses and the one considered in this work is *fusion*. *Fusion* simply stands for removal of intermediate data structures, namely those that are first constructed and then deconstructed. There are two types of fusion that we are interested in.

Mask fusion. Ahead-of-time masking could reduce the number of memory accesses in case of, e.g., matrix-vector multiplication by taking only the elements of interest. In order to achieve such a behavior, a mask should be fused (i.e. transformed into a single operation) with the corresponding operation, for the operation to perform computations only for the elements in the mask. The effect of masking in case of sparse matrix-dense vector multiplication could be seen in figure 1. Ahead-of-time masking reduces the number of memory accesses from 8 to 3.

Kernel fusion. Kernel fusion is responsible for fusing arbitrary operations. In the case of loop-based programming fusion simply stands for joining several loops into one to increase memory locality and reduce the number of required iterations. It is a crucial technique in dense applications and is usually followed by a stage of *polyhedral analysis*. This is extensively exploited in frameworks like TensorFlow and its XLA compiler [2]. A motivating example for general fusion could be seen in listing 1[1], which is a snippet (simplified for demonstration) from Luby's maximal independent set algorithm implementation [22]. As could be seen it is a series of e-wise matrix additions: two consecutive element-wise operations could be fused into one, so `new_members` matrix creation and further iterations are reduced.

Some general-purpose solutions exists that support fusion, e.g., [10] which are based on map/reduce semantics. But in order to support sparse operations they should be able to fuse across index arithmetic, which is not the case. Also at the moment neither [5] nor [24] have adopted the fusion in

[1]The original excerpt is in C++, it is rewritten to ease the demonstration. Call-by-value is assumed.



(a) SpMV not fused with mask (20 loads and stores)

(b) SpMV fused with mask (10 loads and stores)

Fig. 1. Mask fusion example [24]

```
...
-- select node if its probability is > than all its active neighbors

-- @gt is '>' operation, @lor is logical or
let new_members = eWiseAdd gt prob neighbor_max
    iset' = eWiseAdd lor iset new_members in

...
```

Listing 1. Excerpt from Luby's maximal independent set algorithm implementation

their implementations. In this work we propose an approach to support fusion for such applications and outline the overall solution design.

2 SOLUTION

The problem of intermediate data structures is natural for functional programming and a number of approaches for fusion has been designed, namely *partial evaluation, deforestation, supercompilation, distillation* [9, 12, 21, 23]. In this work we will focus on *distillation* since it is able to produce a superlinear improvement for the program being optimized [9].

For succesful fusion the compressed representation should be fuseable, so it should avoid indexing and be natural to functional paradigm. A quad-tree representation [19] looks promising in this case. The implementation of this compressed representation as an algebraic data type could be seen in listing 2, it recursively splits a matrix into four submatrices. Turning back to the successive e-wise matrix additions example, distillation successfully fuses them into one operation where each matrix is iterated only once as also could be seen in listing 2.

If we now define the notion of **intermediate data structure** as the number of times a constructor term within `case` context is encountered during the reduction of the top-level term, i.e. the number of times something is deconstructed with pattern-matching, we could see that the fusion also produces a more effective program, as it could be seen in the table 1, where x/y are reductions, the number of steps to reduce the term to its normal form, and the number of intermediate structures respectively, the numbers at top are the orders of input matrices. Each example firstly was evaluated using the interpreter that counts the number of reductions and intermediate structures. Then it was distilled[2] and evaluated again. Matrices/masks have been taken from [7], converted to q-tree representation and embedded instead of free variables into the corresponding functions. The full list of benchmarks could be found here [1].

It could be noted that `case` $c\ e_0 \ldots e_n$, where c is a constructor, essentially performs a memory read, so the optimization reduces the number of eventual memory reads and corresponding writes

[2]The distiller from [9] was used

```
-- @QNone stands for submatrix which elements are zeroes
data QTree a = QNone
             | QVal a
             | QNode (QTree a) (QTree a) (QTree a) (QTree a)
main = ...
       let new_members = eWiseAdd gt prob neighbor_max
           iset' = eWiseAdd lor iset new_members in
       ...
--gets fused into
main = ...

    let iset' = case iset of
                ... -> case neighbor_max of
                    ... -> case prob of ...
-- @new_members has been eliminated
```

Listing 2. Fusion by means of distillation

Function	Description	# of non-zeroes		
		10^1	10^2	10^3
E-wise successive additions	Original	107 / 22	11293 / 1852	139851 / 20351
	Distilled	44 / 14	6129 / 1433	89215 / 15061
Kronecker with masking	Original	213 / 45	535125 / 92470	6968317 / 1220816
	Distilled	108 / 25	367868 / 67110	3974610 / 867137

Table 1. Distillation results

as well. Another practical example is masking of a kronecker product, since kronecker product performs more operations than matrix-vector multiplication, here it is a more representative example that shows the benefits of masking-fusion. The benefit of optimization is up to **2x** in terms of reductions and up to **1.3x** in terms of intermediate structures, hence it could be stated that distillation is applicable to optimize sparse computations and could be able to speed up practical algorithms like Luby's maximal set. The future work and overall idea behind this is described in the next section.

3 FUTURE WORK

The obvious disadvantage of this approach is that it requires a special domain-specific language amenable to distillation, so it could hardly be integrated into existing implementations like [5, 24]. However, typical CPUs and GPUs are proven to be underutilized [7, 15, 20, 25], i.e., their computing units do not achieve peak performance, suffering from the irregularity of memory accesses incurred by sparsity, so a possible direction could be to design a domain-specific co-processor that is able to execute this distillation-amenable language. Such an approach has found a successful application in image processing [16, 17], programmable networks [11] and machine learning [2, 4].

Notably, in [8] a framework is proposed that is capable of transforming arbitrary Haskell programs into hardware description. It provides datatype-specific memory spaces and divide-and-conquer optimizations (since q-tree representation is divide-and-conquer by its natures, it is a good fit). Each `case` $c\ e_0 \ldots e_n$ expression is generated as an explicit memory read of c and hence distillation is also optimizing the hardware in a sense. The resulting hardware is highly-parallel and pipelined, so it could be a good counterpart to modern CPUs and GPUs.
